Introduction: Type classes

When we want to extend an existing class with a new interface (and so, possibly, with new functionalities) we have essentially four choices:

1. Extending the class itself (not always possible, e.g. API classes)

When we want to extend an existing class with a new interface (and so, possibly, with new functionalities) we have essentially four choices:

1. Extending the class itself (not always possible, e.g. API classes)
2. Creating a new class that extends the original class and the new interface (not always possible, e.g. final classes)

Introduction: Type classes

When we want to extend an existing class with a new interface (and so, possibly, with new functionalities) we have essentially four choices:

1. Extending the class itself (not always possible, e.g. API classes)
2. Creating a new class that extends the original class and the new interface (not always possible, e.g. final classes)
3. Creating a wrapping class that contains the original class and extends the new interface

Introduction: Type classes

When we want to extend an existing class with a new interface (and so, possibly, with new functionalities) we have essentially four choices:

1. Extending the class itself (not always possible, e.g. API classes)
2. Creating a new class that extends the original class and the new interface (not always possible, e.g. final classes)
3. Creating a wrapping class that contains the original class and extends the new interface
4. Using type classes

The last choice is a classical pattern of FP.

Let's introduce type classes with an example. We have this scala interface

```scala
1 trait Summable[T] {
2   def sumElements(list: List[T]): T
3 }
```

and we want that Int and String classes implement it.

Let's introduce type classes with an example. We have this scala interface

```scala
1 trait Summable[T] {
2   def sumElements(list: List[T]): T
3 }
```

and we want that Int and String classes implement it.
Of course we cannot change Int or String classes directly (they are into scala API), so the first option is discarded.

Let's introduce type classes with an example. We have this scala interface

```scala
1 trait Summable[T] {
2   def sumElements(list: List[T]): T
3 }
```

and we want that Int and String classes implement it.
Of course we cannot change Int or String classes directly (they are into scala API), so the first option is discarded.
We could create new classes MyInt and MyStr that extend respectively Int and String but those classes are final, so we cannot work in this way.

Let's introduce type classes with an example. We have this scala interface

```scala
1 trait Summable[T] {
2   def sumElements(list: List[T]): T
3 }
```

and we want that Int and String classes implement it.
Of course we cannot change Int or String classes directly (they are into scala API), so the first option is discarded.
We could create new classes MyInt and MyStr that extend respectively Int and String but those classes are final, so we cannot work in this way.
Surely we can create wrapping classes MyInt and MyStr, but in this way we have now two definitions of Int and of String and it could be messy.

Let's try type classes! We start creating two implicit objects that implement the interface as follows:

```scala
1  implicit object IntSummable extends Summable[Int] {
2    def sumElements(list: List[Int]): Int = list.sum
3  }
4  implicit object StringSummable extends Summable[String] {
5    def sumElements(list: List[String]): String =
6      list.mkString("")
7  }
```

Let's try type classes! We start creating two implicit objects that implement the interface as follows:

```
1  implicit object IntSummable extends Summable[Int] {
2    def sumElements(list: List[Int]): Int = list.sum
3  }
4  implicit object StringSummable extends Summable[String] {
5    def sumElements(list: List[String]): String =
6      list.mkString("")
7  }
```

In this way we can now define a generic method that uses sumElements

```
1  def sumAll[T](l: List[T])(implicit summable: Summable[T]): T
     =
2    summable.sumElements(l)
```

The advantage of this approach is that we can use sumAll method only with Int and String (all the other types will create a compile error) and, because of implict, we don't have to pass summable object to sumAll.

```scala
sumAll(List(1,2,3)) // 6
sumAll(List("Scala ", "is ", "awesome")) // "Scala is
    awesome"
sumAll(List(true, true, false)) // COMPILE ERROR
```

Through extension method we could also use sumAll as method in List of
Int and List of String:

```
1 implicit class ListSummable[A](l: List[A])(implicit summable
     : Summable[A]) {
2   def sumAll: A = summable.sumElements(l)
3 }
```

Through extension method we could also use sumAll as method in List of Int and List of String:

```scala
implicit class ListSummable[A](l: List[A])(implicit summable
    : Summable[A]) {
  def sumAll: A = summable.sumElements(l)
}
```

```scala
List(1,2,3).sumAll //6
List("Scala ", "is ", "awesome").sumAll //"Scala is awesome"
List(true, true, false).sumAll // COMPILE ERROR
```

Let's start with map function:

```
1 def map[A, B](fa: F[A])(f: A => B): F[B]
```

Functors

Let's start with map function:

```
1 def map[A, B](fa: F[A])(f: A => B): F[B]
```

Definition

A functor is a class that has the map method which respects the following laws:

1. **Identity:** given the identity function *id* and a functor *obj* we have that $map(obj)(id) = obj$.

Functors

Let's start with map function:

```
1 def map[A, B](fa: F[A])(f: A => B): F[B]
```

Definition

A functor is a class that has the map method which respects the following laws:

1. **Identity:** given the identity function *id* and a functor *obj* we have that $map(obj)(id) = obj$.

2. **Composition:** given two functions f and g and a functor *obj* we have that $map(map(obj)(f))(g) = map(obj)(g \circ f)$

We'll use type classes to implement functors.
Functors can be represented with the following interface

```
1 trait Functor[F[_]] {
2   def map[A, B](fa: F[A])(f: A => B): F[B]
3 }
```

Let's create List and Option functors.

```scala
implicit object listFunctor: Functor[List] {
  def map[A, B](fa: List[A])(f: A => B): List[B] = fa.map(f)
}
implicit object optionFunctor: Functor[Option] {
  def map[A, B](fa: Option[A])(f: A => B): Option[B] =
  fa match {
    case None => None
    case Some(x) => Some(f(x))
  }
}
```

The first case is easy because List class has already map function (to be honestly, Option has map method too).

Functors - Implementation (3)

As before, we can create a generic method that applies map:

```scala
def applyMap[F[_], A, B](a: F[A])(f: A => B)(implicit
    functor: Functor[F]): F[B] = {
  functor.map(a)(f)
}
applyMap(List(1, 2, 3))(_ + 1) //List(2, 3, 4)
applyMap(Some(1) : Option[Int])(_ + 1) // Some(2)
applyMap(Set(true, true, false))(!_) // COMPILE ERROR
```

Through extension method we could also use applyMap as method of functors:

```scala
implicit class ToFunctor[F[_], A, B](a: F[A])(implicit
    functor: Functor[F]) {
  def applyMap(f: A => B): F[B] = functor.map(a)(f)
}
List(1, 2, 3).applyMap(_ + 1) //List(2, 3, 4)
(Some(1):Option[Int]).applyMap(_ + 1) // Some(2)
Set(true, true, false).applyMap(!_) // COMPILE ERROR
```

Functors Laws

Functors laws are expressed in scala in this way:

```scala
1 def identity(fa: F[A]): Boolean = {
2   def id(x: A): A = x
3   fa.applyMap(id) == fa
4 }
5 def composition(fa: F[A])(f: A => A, g: A => A): Boolean =
6   fa.applyMap(f).applyMap(g) == fa.applyMap(g compose f)
```

We could test these laws through PBT ScalaCheck.

Functors allow to avoid boilerplate code. Let's take Option type. Normally before applying a function on Option we should check if that value is either Some or None through pattern matching:

```scala
1 val a : Option[Int] = Some(20)
2 def f(a : Int) : Int = if (a % 2 == 0) a / 2 else a - 1
3 val ris = (a match {
4    case None => None
5    case Some(b) => Some(f(b))
6 }) //Some(10)
```

Functors reduce code:

```scala
1 val a : Option[Int] = Some(10)
2 def f(a : Int) : Int = if (a % 2 == 0) a / 2 else a - 1
3 val ris = a.applyMap(f) //Some(10)
```

Again, let's start from bind (also called flatMap) and unit methods:

```
1 def bind[A, B](fa: M[A])(f: A => M[B]): M[B]
2 def unit[A](a: A): M[A]
```

Monads

Again, let's start from bind (also called flatMap) and unit methods:

```
1 def bind[A, B](fa: M[A])(f: A => M[B]): M[B]
2 def unit[A](a: A): M[A]
```

Definition

A monad is functor that has bind and unit methods which respect the following laws:

1. **Left identity:** given a function f and an object obj we have that $bind(unit(obj))(f) = f(obj)$.

Monads

Again, let's start from bind (also called flatMap) and unit methods:

```scala
1 def bind[A, B](fa: M[A])(f: A => M[B]): M[B]
2 def unit[A](a: A): M[A]
```

Definition

A monad is functor that has bind and unit methods which respect the following laws:

1. **Left identity:** given a function f and an object obj we have that $bind(unit(obj))(f) = f(obj)$.

2. **Right identity:** given a monad obj we have that $bind(obj)(unit) = obj$

Monads

Again, let's start from bind (also called flatMap) and unit methods:

```
1 def bind[A, B](fa: M[A])(f: A => M[B]): M[B]
2 def unit[A](a: A): M[A]
```

Definition

A monad is functor that has bind and unit methods which respect the following laws:

1. **Left identity:** given a function f and an object obj we have that $bind(unit(obj))(f) = f(obj)$.

2. **Right identity:** given a monad obj we have that $bind(obj)(unit) = obj$

3. **Associativity:** given two functions f and g and a monad obj we have that $bind(bind(obj)(f))(g) = bind(obj)(x \Rightarrow flatMap(f(x))(g))$

We'll use type classes to implement monads.
Monads can be represented with the following interface

```scala
1 trait Monad[M[_]] extends Functor[M] {
2   def bind[A, B](fa: M[A])(f: A => M[B]): M[B]
3   def unit[A](a: A): M[A]
4 }
```

Monads are functors, so have *map* function. Often monads have also another method: *join*. There are standard implementations of *map* and *join* through *bind* and *unit*:

```scala
trait Monad[M[_]] extends Functor[M] {
  def bind[A, B](fa: M[A])(f: A => M[B]): M[B]
  def unit[A](a: A): M[A]
  def join[A](ma: M[M[A]]): M[A] = {
    bind(ma)(m => m)
  }
  override def map[A, B](fa: M[A])(f: A => B): M[B] = {
    bind(fa)(a => unit(f(a)))
  }
}
```

It's possible demonstrate that *bind*(*obj*)(*f*) correspond to *join*(*map*(*obj*)(*f*)).

Let's create List and Option monads.

```scala
implicit object ListMonad extends Monad[List] {
  override def bind[A, B](fa: List[A])(f: A => List[B]):
    List[B] =
    fa.flatMap(f)
  override def unit[A](a: A): List[A] = List(a)
}
implicit object OptionMonad extends Monad[Option] {
  override def bind[A, B](fa: Option[A])(f: A => Option[B]):
    Option[B] =
    fa match {
      case None => None
      case Some(a) => f(a)
    }
  override def unit[A](a: A): Option[A] = Some(a)
}
```

The first case is easy because List class has already flatMap function (to be honestly, Option has flatMap method too).

As before, we can create a generic method that applies bind:

```scala
def bind[M[_], A, B](a: M[A])(f: A => M[B])(implicit monad:
    Monad[M]): M[B] =
  monad.bind(a)(f)
bind(List(1,2,3))((x : Int) => List(x + 1)) //List(2, 3, 4)
bind(Some(1) : Option[Int])((x : Int) => Some(x + 1)) //
    Some(2)
bind(Set(true, true, false))((x : Boolean) => Set(!x)) //
    COMPILE ERROR
```

Monads - Implementation (4)

Through extension method we could also use monads function as method in monads:

```scala
implicit class ToMonad1[M[_], A, B](a: M[A])(implicit monad:
      Monad[M]) {
  lazy val applyUnit: A => M[A] = monad.unit
  def applyBind(f: A => M[B]): M[B] = monad.bind(a)(f)
  def applyMap(f: A => B): M[B] = monad.map(a)(f)
}
implicit class ToMonad2[M[_], A](a: M[M[A]])(implicit monad:
      Monad[M]) {
  lazy val applyJoin: M[A] = monad.join(a)
}
List(1,2,3).bind((x : Int) => List(x + 1)) //List(2, 3, 4)
(Some(1) : Option[Int]).bind((x : Int) => Some(x + 1)) //
      Some(2)
Set(true, true, false).applyBind((x : Boolean) => Set(!x))
      // COMPILE ERROR
```

Monads laws are expressed in scala in this way:

```scala
1 def leftIdentity(a: A)(f: A => M[A]): Boolean =
2   monad.unit(a).applyBind(f) == f(a)
3 def rightIdentity(t: M[A]): Boolean =
4   t.applyBind(t.applyUnit) == t
5 def associativity(t: M[A])(f: A => M[A], g: A => M[A]):
      Boolean =
6   t.applyBind(f).applyBind(g) == t.applyBind((x: A) => f(x).
      applyBind(g))
```

We could test these laws through PBT ScalaCheck.

Why should we use monads instead of functors?
Let's start from a simple example: concatenation of map function.

```
1 val a : Option[Int] = Some(20)
2 val temp = a.applyMap(_ + 1) //Some(22)
3 temp.applyMap(_ + 1) // Some(23)
```

This example works nicely. We start from an Option of Int, after the first step we have an Option of Int on which we apply again the same map function and we finally get an Option of Int.

Differences between Functors and Monads (2)

But, let's try with a new function:

```scala
1 val a : Option[Int] = Some(20)
2 def f(x:Int) : Option[Int] = if (x == 0) None else Some(2 /
      x)
3 val temp1 = a.applyMap(f) // return Some(Some(0))
4 temp1.applyMap(f)// COMPILE ERROR
```

Here we stuck because, after the first step, we got an Option of Option of Int. We could manage this problem and adjust the second function to work with Option of Option of Int, but in this way we would get an Option of Option of Option of Int as result type and we could continue getting more and more layers of Option.

Differences between Functors and Monads (2)

But, let's try with a new function:

```
1 val a : Option[Int] = Some(20)
2 def f(x:Int) : Option[Int] = if (x == 0) None else Some(2 /
    x)
3 val temp1 = a.applyMap(f) // return Some(Some(0))
4 temp1.applyMap(f)// COMPILE ERROR
```

Here we stuck because, after the first step, we got an Option of Option of Int. We could manage this problem and adjust the second function to work with Option of Option of Int, but in this way we would get an Option of Option of Option of Int as result type and we could continue getting more and more layers of Option.
Here monads come to help!

```
1 val temp = a.bind(f) // return Some(0)
2 temp.bind(f) //None
```

We could continue to apply bind endless, without change the return type.

Let's start from an example

```scala
1 val v = List(Option(1), None, Option(3))
2 val f1: Int => String = _ + "a"
3 v.applyMap(x => x.applyMap(f1)) //List(Some(1a), None, Some(3a))
```

If we have a functors of a functor we can compose *map* in a simple (and intuitive) way: *map(v)(x => map(x)(f1))*.

Again, let's start from an example

```scala
val v = List(Option(1), None, Option(3))
val f2: Int => List[Option[String]] = x => List(Some(x + "a"
    ))
v.applyBind(x => x.applyBind(f2)) // COMPILE ERROR
```

If we have a monads of a monads we **cannot** compose *bind* in a simple (and intuitive) way: $bind(v)(x => bind(x)(f2))$. We would have type mismatch error.

A solution could be

```scala
1 v.applyBind {
2   case None => default
3   case Some(x) => f2(x)
4 } //List(Some(1a), None, Some(3a))
```

This conduces to boilerplate code (again...).
Note also that now Option could be or not a monad because we don't use bind or unit of Option. So the problem is related to monad which internal type is generic.

Transformer

Monad transformers are monad which internal type is generic (with generic instantiated with non-generic type), so they are monad of type $M1[M2[A]]$ with an additional method *lift*.

Transformer

Monad transformers are monad which internal type is generic (with generic instantiated with non-generic type), so they are monad of type $M1[M2[A]]$ with an additional method *lift*. They have the same laws of monad, plus:

1. Law 1: given an object *obj* we have that $lift(unit(obj)) = unit(obj)$ where unit call on the left is monad method and unit on the right is transformer method.

Monad transformers are monad which internal type is generic (with generic instantiated with non-generic type), so they are monad of type $M1[M2[A]]$ with an additional method *lift*. They have the same laws of monad, plus:

1. Law 1: given an object *obj* we have that $lift(unit(obj)) = unit(obj)$ where unit call on the left is monad method and unit on the right is transformer method.

2. Law 2: given a function f and a monad m we have that $lift(bind(m)(f)) = bind(lift(m))(lift \circ f)$ where bind call on the left is monad method and bind on the right is transformer method.

We'll use type classes to implement monad transformers.

```
1 trait Transformer[M1[_], M2[_]] {
2   implicit def monadM1: Monad[M1]
3   def bind[A, B](fa: M1[M2[A]])(f: A => M1[M2[B]]): M1[M2[B
     ]]
4   def unit[A](a: A): M1[M2[A]]
5   def lift[A](fa: M1[A]): M1[M2[A]]
6   def join[A](fa: M1[M2[M1[M2[A]]]]): M1[M2[A]] =
7     bind(fa)(m => m)
8   def map[A, B](fa: M1[M2[A]])(f: A => B): M1[M2[B]] =
9     bind(fa)(a => unit(f(a)))
10 }
```

Transformer - Implementation (2)

Let's create Option transformer, called OptionT.

```scala
1  trait OptionT[M1[_]] extends Transformer[M1, Option] {
2    override def bind[A, B](fa: M1[Option[A]])(f: A => M1[
       Option[B]]): M1[Option[B]] = {
3      monadM1.bind(fa) {
4        case None => monadM1.unit(None)
5        case Some(a) => f(a)
6      }
7    }
8    override def lift[A](fa: M1[A]): M1[Option[A]] =
9      monadM1.bind(fa)(a => unit(a))
10   override def unit[A](a: A): M1[Option[A]] = monadM1.unit(
       Some(a))
11 }
```

We can instantiate it on list, provided implicit ListMonad, in this way:

```scala
1  implicit object ListOptionT extends OptionT[List] {
2    override implicit val monadM1: Monad[List] = implicitly
3  }
```

Transformer - Implementation (3)

Through extension method we could also use transformer function as method in transformer:

```scala
implicit class ToTransformer1[M1[_], M2[_], A, B](a: M1[M2[A]])(implicit transformer: Transformer[M1, M2]) {
  lazy val applyUnitT: A => M1[M2[A]] = transformer.unit
  def applyMapT(f: A => B): M1[M2[B]] = transformer.map(a)(f)
  def applyBindT(f: A => M1[M2[B]]): M1[M2[B]] = transformer.bind(a)(f)
}
implicit class ToTransformer2[M1[_], M2[_], A, B](fa: M1[A])(implicit transformer: Transformer[M1, M2]) {
  lazy val applyLiftT: M1[M2[A]] = transformer.lift(fa)
}
implicit class ToTransformer3[M1[_], M2[_], A, B](fa: M1[M2[M1[M2[A]]]])(implicit transformer: Transformer[M1, M2]) {
  lazy val applyJoinT: M1[M2[A]] = transformer.join(fa)
}
```

Transformer Laws

Transformer laws are expressed in scala in this way:

```scala
1 def law1(a: A): Boolean =
2   transformer.monadM1.unit(a).applyLiftT == transformer.unit
    (a)
3 def law2(m: M1[A])(f: A => M1[A]): Boolean =
4   transformer.lift(transformer.monadM1.bind(m)(f)) ==
    transformer.lift(m).applyBindT(transformer.lift[A] _
    compose f)
5 def leftIdentity(a: A)(f: A => M1[M2[A]]): Boolean =
6   transformer.unit(a).applyBindT(f) == f(a)
7 def rightIdentity(t: M1[M2[A]]): Boolean =
8   t.applyBindT(t.applyUnitT) == t
9 def associativity(t: M1[M2[A]])(f: A => M1[M2[A]], g: A =>
    M1[M2[A]]): Boolean =
10  t.applyBindT(f).applyBindT(g) == t.applyBindT((x: A) => f(
    x).applyBindT(g))
```

We could test these laws through PBT ScalaCheck.
